This manuscript was compiled on March 15, 2023

Descriptive statistics for parametric models currently heavily rely on the accuracy of distributional assumptions. Here, based on the invariant structures of unimodal distributions, a series of sophisticated yet efficient estimators, robust to both gross errors and departures from parametric assumptions, are proposed for estimating mean and central moments with insignificant asymptotic biases for common continuous unimodal distributions. This article also illuminates the understanding of the common nature of probability distributions and the measures of them.

orderliness | invariant | unimodal | adaptive estimation | U -statistics

The asymptotic inconsistencies between sample mean (\bar{x}) and nonparametric robust location estimators in asymmetric distributions on the real line have been noticed for more than two centuries (1), yet remain unsolved. Strictly speaking, it is unsolvable because by trimming, some information about the original distribution is removed, making it impossible to estimate the values of the removed parts without distributional assumptions. Newcomb (1886, 1912) provided the first modern approach to this problem by developing a class of estimators that gives "less weight to the more discordant observations" (2, 3). In 1964, Huber (4) used the minimax procedure to obtain M-estimator for the contaminated normal distribution, which has played a pre-eminent role in the later development of robust statistics. As previously demonstrated, under growing asymmetric departures from normality, the bias of the Huber M-estimator increases rapidly. This is a common issue in parametric estimations. For example, He and Fung (1999) constructed (5) a robust M-estimator for the two-parameter Weibull distribution, from which all moments can be calculated from its estimated parameters. As expected, it is inadequate for the gamma, Perato, lognormal, and the generalized Gaussian distributions (SI Dataset S1). Another old and interesting approach is arithmetically computing the parameters using one or more L -statistics as inputs, such as percentile estimators. Examples for the Weibull distribution, the reader is referred to Menon (1963) (6), Dubey (1967) (7), Hassanein (1971) (8), Marks (2005) (9), and Boudt, Caliskan, and Croux (2011) (10)'s works. At the outset of the study of percentile estimators, it was known that they arithmetically utilizes the invariant structures of probability distributions (6, 11, 12). Maybe such estimators can be named as I -statistics. Formally, an estimator is classified as an I -statistic if it asymptotically satisfies $I(LE_1, \dots, LE_l) = (\theta_1, \dots, \theta_q)$ for the distribution it is consistent with, where LEs are calculated with the use of L -statistics, I is defined using arithmetic operations and constants, but it may also incorporate other functions, and θ s are the population parameters it estimates. A subclass of I -statistics, arithmetic I -statistics, is defined as LEs are L -statistics, I is solely defined using arithmetic operations and constants. Since some percentile estimators use the logarithmic

function to transform all random variables before compute the L -statistics, a percentile estimator might not always be an arithmetic I -statistic (7). In this article, two subclasses of I -statistics are introduced, arithmetic I -statistics and quantile I -statistics. Examples of quantile I -statistics will be discussed later. Based on L -statistics, I -statistics are naturally robust. Compared to probability density functions (pdfs) and cumulative distribution functions (cdfs), the quantile functions of many parametric distributions are often more elegant. Since the expectation of an L -statistic can often be expressed as an integral of the quantile function, I -statistics are often analytically obtainable. However, the performance of the above examples is often worse than that of the robust M -statistics when the distributional assumption is violated (SI Dataset S1). Even when distributions such as the Weibull and gamma belong to the same larger family, the generalized gamma distribution, a misassumption can still result in substantial biases, rendering the approach ill-suited.

In previous research on semiparametric robust mean estimation, the binomial mean (BM_ϵ) is still inconsistent for any skewed distribution if $\epsilon > 0$, although its asymptotic bias is much smaller than that of the trimmed mean (if $\epsilon \rightarrow 0$, $BM \rightarrow \mu$, since the alternating sum of binomial coefficients is zero). All robust location estimators commonly used are symmetric due to the universality of the symmetric distributions. One can construct an asymmetric weighted average that is consistent for a semiparametric class of skewed distributions. This approach has been investigated previously, but its lack of symmetry makes it suitable only for certain applications (13). Moving from semiparametrics to parametrics, an ideal robust location estimator would have a non-sample-dependent breakdown point (defined in Subsection ??) and be consistent with any symmetric distribution and a skewed distribution with finite second moments. This is called an invariant mean. Based

Significance Statement

Bias, variance, and contamination are the three main errors in statistics. Consistent robust estimation is unattainable without parametric assumptions. Here, based on a paradigm shift inspired by mean-median-mode inequality, Bickel-Lehmann spread, and adaptive estimation, invariant moments are proposed as a means of achieving near-consistent and robust estimations of moments, even in scenarios where moderate violations of distributional assumptions occur, while the variances are sometimes smaller than those of the sample moments.

on the mean-symmetric weighted average-median inequality, the recombined mean is defined as

$$rm_{d,\epsilon,n} := \lim_{c \rightarrow \infty} \left(\frac{(\text{SWA}_{\epsilon,n} + c)^{d+1}}{(\text{median} + c)^d} - c \right),$$

where d is the key factor for bias correction, $\text{SWA}_{\epsilon,n}$ is $\text{BM}_{\epsilon,n}$ in the first three Subsections, but other symmetric weighted averages can also be employed in practice as long as the inequalities hold. The following theorem shows the significance of this arithmetic I -statistic.

Theorem .1. *If the second moments are finite, $rm_{d \approx 0.375, \epsilon = \frac{1}{8}}$ is a consistent mean estimator for the exponential and any symmetric distributions and the Pareto distribution with quantile function $Q(p) = x_m(1-p)^{-\frac{1}{\alpha}}$, $x_m > 0$, when $\alpha \rightarrow \infty$.*

Proof. Finding d and ϵ that make $rm_{d,\epsilon}$ a consistent mean estimator is equivalent to finding the solution of $E[rm_{d,\epsilon}] = E[X]$. Rearranging the definition, $rm_{d,\epsilon} = \lim_{c \rightarrow \infty} \left(\frac{(\text{BM}_{\epsilon} + c)^{d+1}}{(\text{median} + c)^d} - c \right) = (d+1)\text{BM}_{\epsilon} - d\text{median} = \mu$. So, $d = \frac{\mu - \text{BM}_{\epsilon}}{\text{BM}_{\epsilon} - \text{median}}$. The quantile function of the exponential distribution is $Q(p) = \ln\left(\frac{1}{1-p}\right)\lambda$. $E[x] = \lambda$. $E[\text{median}] = Q\left(\frac{1}{2}\right) = \ln 2\lambda$. For the exponential distribution, the expectation of $\text{BM}_{\frac{1}{8}}$ is $E\left[\text{BM}_{\frac{1}{8}}\right] = \lambda\left(1 + \ln\left(\frac{46656}{8575\sqrt{35}}\right)\right)$. Obviously, the scale parameter λ can be canceled out, $d \approx 0.375$. The proof of the second assertion follows directly from the co-incidence property. For any symmetric distribution with a finite second moment, $E[\text{BM}_{\epsilon}] = E[\text{median}] = E[X]$. Then $E[rm_{d,\epsilon}] = \lim_{c \rightarrow \infty} \left(\frac{(E[X] + c)^{d+1}}{(E[X] + c)^d} - c \right) = E[X]$. The proof for the Pareto distribution is more general. The mean of the Pareto distribution is given by $\frac{\alpha x_m}{\alpha - 1}$. The d value with two unknown percentiles p_1 and p_2 for the Pareto distribution is $d_{\text{Pareto}} = \frac{\frac{\alpha x_m}{\alpha - 1} - x_m(1-p_1)^{-\frac{1}{\alpha}}}{x_m(1-p_1)^{-\frac{1}{\alpha}} - x_m(1-p_2)^{-\frac{1}{\alpha}}}$. Since any weighted average can be expressed as an integral of the quantile function, $\lim_{\alpha \rightarrow \infty} \frac{\frac{\alpha}{(1-p_1)^{-1/\alpha} - (1-p_2)^{-1/\alpha}} - \frac{\ln(1-p_1)+1}{\ln(1-p_1)-\ln(1-p_2)}}{\frac{\alpha}{(1-p_1)^{-1/\alpha} - (1-p_2)^{-1/\alpha}}} = -\frac{\ln(1-p_1)+1}{\ln(1-p_1)-\ln(1-p_2)}$, the d value for the Pareto distribution approaches that of the exponential distribution as $\alpha \rightarrow \infty$, regardless of the type of weighted average used. This completes the demonstration. \square

Theorem .1 implies that for the Weibull, gamma, Pareto, lognormal and generalized Gaussian distribution, $rm_{d \approx 0.375, \epsilon = \frac{1}{8}}$ is consistent for at least one particular case of these two-parameter distributions. The biases of $rm_{d \approx 0.375, \epsilon = \frac{1}{8}}$ for distributions with skewness between those of the exponential and symmetric distributions are tiny (SI Dataset S1). $rm_{d \approx 0.375, \epsilon = \frac{1}{8}}$ has excellent performance for all these common unimodal distributions (SI Dataset S1).

Besides introducing the concept of invariant mean, the purpose of this paper is to demonstrate that, in light of previous works, the estimation of central moments can be transformed into a location estimation problem by using U -statistics, the central moment kernel distributions possess desirable properties, and a series of sophisticated yet efficient robust estimators can be constructed whose biases are typically smaller than the variances (as seen in Table ?? for $n = 5400$) for unimodal distributions.

Background and Main Results

A. Invariant mean. It has long been known that a theoretical model can be adjusted to fit the first two moments of the observed data. A continuous distribution belonging to a location-scale family takes the form $F(x) = F_0\left(\frac{x-\mu}{\lambda}\right)$, where F_0 is a "standard" distribution. Therefore, $F(x) = Q^{-1}(x) \rightarrow x = Q(p) = \lambda Q_0(p) + \mu$. Thus, any weighted average can be expressed as $\lambda \text{WA}_0(\epsilon) + \mu$, where $\text{WA}_0(\epsilon)$ is an integral of $Q_0(p)$ according to the definition of the weighted average. The simultaneous cancellation of μ and λ in $\frac{(\lambda\mu_0 + \mu) - (\lambda\text{BM}_0(\epsilon) + \mu)}{(\lambda\text{BM}_0(\epsilon) + \mu) - (\lambda\text{median}_0 + \mu)}$ ensures that d is a constant. Consequently, the roles of BM_{ϵ} and median in $rm_{d,\epsilon}$ can be replaced by any weighted averages, although only symmetric weighted averages are considered in defining the invariant mean.

The performance in heavy-tailed distributions can be further improved by constructing the quantile mean as

$$qm_{d,\epsilon,n} := \hat{Q}_n \left(\left(\hat{F}_n(\text{SWA}_{\epsilon,n}) - \frac{1}{2} \right) d + \hat{F}_n(\text{SWA}_{\epsilon,n}) \right),$$

provided that $\hat{F}_n(\text{SWA}_{\epsilon,n}) \geq \frac{1}{2}$, where $\hat{F}_n(x)$ is the empirical cumulative distribution function of the sample, \hat{Q}_n is the sample quantile function. The most popular method for computing the sample quantile function was proposed by Hyndman and Fan in 1996 (14). To minimize the finite sample bias, here, $\hat{F}_n(x) := \frac{1}{n} \left(\frac{x - X_{sp}}{X_{sp+1} - X_{sp}} + sp \right)$, where $sp = \sum_{i=1}^n \mathbf{1}_{X_i \leq x}$, $\mathbf{1}_A$ is the indicator of event A . The solution of $\hat{F}_n(\text{SWA}_{\epsilon,n}) < \frac{1}{2}$ is reversing the percentile by $1 - \hat{F}_n(\text{SWA}_{\epsilon,n})$, the obtained percentile is also reversed. Without loss of generality, in the following discussion, only the case where $\hat{F}_n(\text{SWA}_{\epsilon,n}) \geq \frac{1}{2}$ is considered. Moreover, in extreme heavy-tailed distributions, the calculated percentile can exceed the breakdown point of SWA_{ϵ} , so the percentile will be modified to $1 - \epsilon$ if this occurs. The quantile mean uses the location-scale invariant in a different way as shown in the following proof.

Theorem A.1. *$qm_{d \approx 0.321, \epsilon = \frac{1}{8}}$ is a consistent mean estimator for the exponential, Pareto ($\alpha \rightarrow \infty$) and any symmetric distributions provided that the second moments are finite.*

Proof. Similarly, rearranging the definition, $d = \frac{F(\mu) - F(\text{BM}_{\epsilon})}{F(\text{BM}_{\epsilon}) - \frac{1}{2}}$. The cdf of the exponential distribution is $F(x) = 1 - e^{-\lambda^{-1}x}$, $\lambda \geq 0$, $x \geq 0$, the expectation of BM_{ϵ} can be expressed as $\lambda \text{BM}_0(\epsilon)$, so $F(\text{BM}_{\epsilon})$ is free of λ . When $\epsilon = \frac{1}{8}$, $d = \frac{-e^{-1} + e^{-\left(1 + \ln\left(\frac{46656}{8575\sqrt{35}}\right)\right)}}{\frac{1}{2} - e^{-\left(1 + \ln\left(\frac{46656}{8575\sqrt{35}}\right)\right)}} \approx 0.321$. The proof of the symmetric case is similar. Since for any symmetric distribution with a finite second moment, $F(E[\text{BM}_{\epsilon}]) = F(\mu) = \frac{1}{2}$. Then, the expectation of the quantile mean is $qm_{d,\epsilon} = F^{-1}\left(\left(F(\mu) - \frac{1}{2}\right)d + F(\mu)\right) = F^{-1}\left(0 + F(\mu)\right) = \mu$.

For the assertion related to the Pareto distribution, the cdf of it is $1 - \left(\frac{x_m}{x}\right)^{\alpha}$. So, the d value with two unknown percentile p_1 and p_2 is

$$d_{\text{Pareto}} = \frac{1 - \left(\frac{x_m}{\frac{\alpha x_m}{\alpha - 1}}\right)^{\alpha} - \left(1 - \left(\frac{x_m}{x_m(1-p_1)^{-\frac{1}{\alpha}}}\right)^{\alpha}\right)}{\left(1 - \left(\frac{x_m}{x_m(1-p_1)^{-\frac{1}{\alpha}}}\right)^{\alpha}\right) - \left(1 - \left(\frac{x_m}{x_m(1-p_2)^{-\frac{1}{\alpha}}}\right)^{\alpha}\right)} = \frac{1 - \left(\frac{\alpha - 1}{\alpha}\right)^{\alpha - p_1}}{p_1 - p_2}. \text{ When } \alpha \rightarrow \infty, \left(\frac{\alpha - 1}{\alpha}\right)^{\alpha} = \frac{1}{e}. \text{ The } d \text{ value for the exponential distribution is identical, since } d_{\text{exp}} =$$

$$\frac{(1-e^{-1}) - \left(1-e^{-\ln\left(\frac{1}{1-p_1}\right)}\right)}{\left(1-e^{-\ln\left(\frac{1}{1-p_1}\right)}\right) - \left(1-e^{-\ln\left(\frac{1}{1-p_2}\right)}\right)} = \frac{1-\frac{1}{e}-p_1}{p_1-p_2}. \quad \text{All results are now proven.} \quad \square$$

The definitions of location and scale parameters are such that they must satisfy $F(x; \lambda, \mu) = F\left(\frac{x-\mu}{\lambda}; 1, 0\right)$. Recall that $x = \lambda Q_0(p) + \mu$, so the percentile of any weighted average is free of λ and μ , which guarantees the validity of the quantile mean. The quantile mean is a quantile I -statistic. Specifically, an estimator is classified as a quantile I -statistic if LEs are percentiles of a distribution obtained by plugging L -statistics into a cumulative distribution function and I is defined with arithmetic operations, constants and quantile functions. $qm_{d \approx 0.321, \epsilon = \frac{1}{8}}$ works better in the fat-tail scenarios (SI Dataset S1). Theorem .1 and A.1 show that $rm_{d \approx 0.375, \epsilon = \frac{1}{8}}$ and $qm_{d \approx 0.321, \epsilon = \frac{1}{8}}$ are both consistent mean estimators for any symmetric distribution and a skewed distribution with finite second moments. It's evident that the breakdown points of $rm_{d \approx 0.375, \epsilon = \frac{1}{8}}$ and $qm_{d \approx 0.321, \epsilon = \frac{1}{8}}$ are both $\frac{1}{8}$. Therefore they are all invariant means.

To study the impact of the choice of SWAs in rm and qm , it is constructive to recall that a symmetric weighted average is a linear combination of symmetric quantile averages. While using a less-biased symmetric weighted average can generally enhance performance (SI Dataset S1), there is a greater risk of violation in the semiparametric framework. However, the mean-SWA-median inequality is robust to slight fluctuations of the SQA function of the underlying distribution. Suppose the SQA function is generally decreasing in $[0, u]$, but increasing in $[u, \frac{1}{2}]$, since $1-2\epsilon$ of the symmetric quantile averages will be included in the computation of SWA_ϵ , as long as $|u - \frac{1}{2}| \ll 1-2\epsilon$, and other portions of the SQA function satisfy the inequality constraints that define the ν th orderliness on which the SWA_ϵ is based, the mean-SWA-median inequality will still hold. This is due to the violation being bounded (15) and therefore cannot be extreme for unimodal distributions. For instance, the SQA function is non-monotonic when the shape parameter of the Weibull distribution $\alpha > \frac{1}{1-\ln(2)} \approx 3.259$ as shown in the previous article, the violation of the third orderliness is also close to this parameter, yet the mean-BM $_{\frac{1}{8}}$ -median inequality is still valid when $\alpha \leq 3.322$. Another key factor in determining the risk of violation is the skewness of the distribution. In the previous article, it was demonstrated that in a family of distributions differing by a skewness-increasing transformation in van Zwet's sense, the violation of orderliness, if it happens, often only occurs when the distribution is nearly symmetrical (16). The over-corrections in rm and qm are dependent on the SWA_ϵ -median difference, which can be a reasonable measure of skewness (17, 18), implying that the over-correction is often tiny with a moderate d . This qualitative analysis provides another perspective, in addition to the bias bounds (15), that rm and qm based on the mean-SWA-median inequality are generally safe.

B. Robust estimations of the central moments. In 1976, Bickel and Lehmann, in their third paper of the landmark series *Descriptive Statistics for Nonparametric Models* (19), generalized a class of estimators called "measures of disperse," which is now often named as Bickel-Lehmann dispersion. As an example,

they proposed a first version of the trimmed standard deviation, $\hat{\tau}^2(F; \epsilon) \equiv \tau^2(F; \epsilon)$, for independent and identically distributed random variables X with a distribution F , where $\tau^2(F; \epsilon) = \frac{1}{1-2\epsilon} \int_{Q(\epsilon)}^{Q(1-\epsilon)} y dG(y)$, Q is the quantile function of G , G is the distribution of $Y = X^2$. Obviously, when $\epsilon = 0$, the result is equivalent to the second raw moment. In 1979, in the same series (20), they explored another class of estimators called "measures of spread," which "does not require the assumption of symmetry." From that, a popular efficient scale estimator, the Rousseeuw-Croux scale estimator (21), was derived in 1993, but the importance of tackling the symmetry assumption has been greatly underestimated. In the final section of that paper (20), they considered another two possible versions of the trimmed standard deviations, which were modified here for comparison,

$$\left[n\left(\frac{1}{2} - \epsilon\right)\right]^{-\frac{1}{2}} \left[\sum_{i=\frac{n}{2}}^{n(1-\epsilon)} [X_i - X_{n-i+1}]^2 \right]^{\frac{1}{2}}, \quad [1]$$

and

$$\left[\binom{n}{2} (1 - \epsilon - \gamma\epsilon)\right]^{-\frac{1}{2}} \left[\sum_{i=\binom{n}{2}\epsilon}^{\binom{n}{2}(1-\gamma\epsilon)} (X - X')_i^2 \right]^{\frac{1}{2}}, \quad [2]$$

where $(X - X')_1 \leq \dots \leq (X - X')_{\binom{n}{2}}$ are the order statistics of the "pseudo-sample". The paper ended with, "We do not know a fortiori which of the measures [1] or [2] is preferable and leave these interesting questions open."

Observe that the kernel of the unbiased estimation of the second central moment by using U -statistic is $\psi_2(x_1, x_2) = \frac{1}{2}(x_1 - x_2)^2$. If adding the $\frac{1}{2}$ term in [2], as $\epsilon \rightarrow 0$, the result is equivalent to the standard deviation estimated by using U -statistic (also noted by Janssen, Serfling, and Veraverbeke in 1987) (22). In fact, they also showed that, when ϵ is 0, [2] is $\sqrt{2}$ times the standard deviation.

To address their open questions, the nomenclature used in this paper is introduced as follows:

Nomenclature. Given a robust estimator $\hat{\theta}$. The first part of the name of the robust statistic defined in this paper is a name that indicates the type of estimator, and the second part is the name of the population parameter θ that the estimator is consistent with as $\epsilon \rightarrow 0$. The abbreviation of the estimator is formed by combining the initial letter(s) of the first part with the common abbreviation of the consistent estimator that measures the population parameter. If the estimator is symmetric and not a U -statistic, ϵ is indicated in the subscript of the abbreviation of the estimator. For asymmetric estimators, the corresponding γ is also indicated after ϵ . For weighted U -statistics, the breakdown point of the location estimator is indicated, except the median.

In the previous article on semiparametric robust mean estimation, it was shown that the bias of a reasonable robust estimator should be monotonic with respect to the breakdown point in a semiparametric distribution and, naturally, its name should align with the consistent estimator. The trimmed standard deviation following this nomenclature is $Tsd_{\epsilon, \gamma, n} := \left[TM_{\epsilon, \gamma} \left((\psi_2(X_{N_1}, X_{N_2}))_{N=1}^{\binom{n}{2}} \right) \right]^{-\frac{1}{2}}$, where $TM_{\epsilon, \gamma}(Y)$ denotes

the ϵ, γ -trimmed mean with the sequence $(\psi_2(X_{N_1}, X_{N_2}))_{N=1}^{\binom{n}{2}}$ as an input. Removing the square root yields the trimmed variance ($\text{Tvar}_{\epsilon, \gamma, n}$). It is now very clear that this definition, essentially the same as [2], should be preferable. Not only because it is essentially a trimmed U -statistic for the standard deviation but also because the γ -orderliness of the second central moment kernel distribution is ensured by the next exciting theorem.

Theorem B.1. *The second central moment kernel distribution generated from any continuous unimodal distribution is γ -ordered, if $\gamma \geq 1$.*

Proof. Let $Q(p)$, $0 \leq p \leq 1$, denote the quantile of the continuous unimodal distribution $f_X(x)$. The corresponding probability density is $f(Q(p))$. Generating the distribution of the pair $(Q(p_i), Q(p_j))$, $i < j$, $p_i < p_j$, the corresponding probability density is $f_{X,X}(Q(p_i), Q(p_j)) = 2f(Q(p_i))f(Q(p_j))$. Transforming the pair $(Q(p_i), Q(p_j))$, $i < j$, by the function $\Phi(x_1, x_2) = x_1 - x_2$, the pairwise difference distribution has a mode that is arbitrary close to $M - M = 0$. The monotonic increasing of the pairwise difference distribution was first implied in its unimodality proof done by Hodges and Lehmann in 1954 (23). Whereas they used induction to get the result, Dharmadhikari and Jogdeo in 1982 (24) provided a modern proof of the unimodality using Khintchine's representation (25). Assuming absolute continuity, Purkayastha (26) introduced a much simpler proof in 1998. Transforming the pairwise difference distribution by squaring and multiplying by $\frac{1}{2}$ does not change the monotonicity, making the pdf become monotonically decreasing with mode at zero. In the previous semiparametric robust mean estimation article, it was proven that a right skewed distribution with a monotonic decreasing pdf is always γ -ordered, if $\gamma \geq 1$, which gives the desired result. \square

Remark. The assumption of continuity of distributions is important for monotonicity because, unlike in the continuous case, it is possible to obtain pairs with the same value for a discrete distribution. For example, let the probabilities of the singletons $\{1\}$, $\{2\}$, $\{3\}$, $\{4\}$ and $\{5\}$ of a probability mass function of a discrete probability distribution be $\frac{1}{11}$, $\frac{4}{11}$, $\frac{3}{11}$, $\frac{2}{11}$, and $\frac{1}{11}$, respectively. This is a unimodal distribution, but the corresponding ψ_2 distribution is non-monotonic, whose singletons $\{0\}$, $\{0.5\}$, $\{2\}$, $\{4.5\}$ and $\{8\}$ have probabilities $\frac{21}{66}$, $\frac{24}{66}$, $\frac{2}{14}$, $\frac{6}{66}$, and $\frac{1}{66}$, respectively.

Previously, it was shown that any symmetric distribution with a finite second moment is ν th ordered, indicating that orderliness does not require unimodality, e.g., a symmetric bimodal distribution is also ordered. Examples from the Weibull distribution show that unimodality does not guarantee orderliness. Theorem B.1 reveals another profound relationship between unimodality and orderliness, which is sufficient for trimming inequality.

In 1928, Fisher constructed k -statistics as unbiased estimators of cumulants (27). Halmos (1946) proved that the functional θ admits an unbiased estimator if and only if it is a regular statistical functional of degree k and showed a relation of symmetry, unbiasedness and minimum variance (28). In 1948, Hoeffding generalized U -statistics (29) which enable the derivation of a minimum-variance unbiased estimator from each unbiased estimator of an estimable parameter. Heffernan

(1997) (30) obtained an unbiased estimator of the k th central moment by using U -statistics and demonstrated that it is the minimum variance unbiased estimator for distributions with finite moments (31, 32). In 1976, Saleh generalized the Hodges-Lehmann estimator (33) to the trimmed H-L mean (which he named "Wilcoxon one-sample statistic") (34). In 1984, Serfling pointed out the speciality of Hodges-Lehmann estimator, which is neither a simple L -statistic nor a U -statistic, and considered the generalized L -statistics and U -statistic structure (35). Also in 1984, Janssen and Serfling and Veraverbeke (36) showed that the Bickel-Lehmann spread also belongs to the same class. It gradually became clear that the Hodges-Lehmann estimator, trimmed H-L mean and trimmed standard deviation are all trimmed U -statistics (37–39).

Extending the trimmed U -statistic to weighted U -statistic, i.e., replacing the trimmed mean with weighted average. The weighted k th central moment ($k \leq n$) is defined as,

$$Wkm_{\epsilon, \gamma, n} := WA_{\epsilon, \gamma, n} \left((\psi_k(X_{N_1}, \dots, X_{N_k}))_{N=1}^{\binom{n}{k}} \right),$$

where X_{N_1}, \dots, X_{N_k} are the n choose k elements from X , $\psi_k(x_1, \dots, x_k) = \sum_{j=0}^{k-2} (-1)^j \left(\frac{1}{k-j} \right) \sum (x_{i_1}^{k-j} \dots x_{i_{j+1}}) + (-1)^{k-1} (k-1) x_1 \dots x_k$, the second summation is over $i_1, \dots, i_{j+1} = 1$ to k with $i_1 < \dots < i_{j+1}$ (30). Despite the complexity, the structure of the k th central moment kernel distributions can be elucidated by decomposing.

Theorem B.2. *For each pair $(Q(p_i), Q(p_j))$ of the original distribution, let $x_1 = Q(p_i)$ and $x_k = Q(p_j)$, $\Delta = Q(p_i) - Q(p_j)$. The k th central moment kernel distribution, $k > 2$, can be seen as a mixture distribution and each of the components has the support $(-\left(\frac{k}{3+(-1)^k}\right)^{-1}(-\Delta)^k, \frac{1}{k}(-\Delta)^k)$.*

Proof. Generating the distribution of the k -tuple $(Q(p_{i_1}), \dots, Q(p_{i_k}))$, $k > 2$, $i_1 < \dots < i_k$, $p_{i_1} < \dots < p_{i_k}$, the corresponding probability density is $f_{X, \dots, X}(Q(p_{i_1}), \dots, Q(p_{i_k})) = k! f(Q(p_{i_1})) \dots f(Q(p_{i_k}))$. Transforming the distribution of the k -tuple by the function $\psi_k(x_1, \dots, x_k)$, denoting $\bar{\Delta} = \psi_k(Q(p_{i_1}), \dots, Q(p_{i_k}))$. The probability $f_{\Xi_k}(\bar{\Delta}) = \sum_{\bar{\Delta} = \psi_k(Q(p_{i_1}), \dots, Q(p_{i_k}))} f_{X, \dots, X}(Q(p_{i_1}), \dots, Q(p_{i_k}))$ is the summation of the probabilities of all k -tuples such that $\bar{\Delta}$ is equal to $\psi_k(Q(p_{i_1}), \dots, Q(p_{i_k}))$. The following Ξ_k is equivalent.

Ξ_k : Every pair with a difference equal to $\Delta = Q(p_{i_1}) - Q(p_{i_k})$ can generate a pseudodistribution (but the integral is not equal to 1, so "pseudo") such that x_2, \dots, x_{k-1} exhaust all combinations under the inequality constraints, i.e., $Q(p_{i_1}) = x_1 < x_2 < \dots < x_{k-1} < x_k = Q(p_{i_k})$. The combination of all the pseudodistributions with the same Δ is ξ_Δ . The combination of ξ_Δ , i.e., from $\Delta = 0$ to $Q(0) - Q(1)$, is Ξ_k .

The support of ξ_Δ is the extrema of ψ_k subject to the inequality constraints. Using the Lagrange multiplier, one can easily determine the only critical point at $x_1 = \dots = x_k = 0$, where $\psi_k = 0$. Other candidates are within the boundaries, i.e., $\psi_k(x_1 = x_1, x_2 = x_k, \dots, x_k = x_k)$, \dots , $\psi_k(x_1 = x_1, \dots, x_i = x_1, x_{i+1} = x_k, \dots, x_k = x_k)$, \dots , $\psi_k(x_1 = x_1, \dots, x_i = x_1, x_{i+1} = x_k, \dots, x_k = x_k)$ can be divided into k groups. If $\frac{k+1-i}{2} \leq j \leq \frac{k-1}{2}$, from $j+1$ st to $k-j$ th group, the j th group has $i \binom{i-1}{g-j-1} \binom{k-i}{j}$ terms having the form

373 $(-1)^{g+1} \frac{1}{k-g+1} x_1^{k-j} x_k^j$, from $k-j+1$ th to $i+j$ th group, the g th
 374 group has $i \binom{i-1}{g-j-1} \binom{k-i}{j} + (k-i) \binom{k-i-1}{j-k+g-1} \binom{i}{k-j}$ terms hav-
 375 ing the form $(-1)^{g+1} \frac{1}{k-g+1} x_1^{k-j} x_k^j$. If $j < \frac{k+1-i}{2}$, from $j+1$ st
 376 to $i+j$ th group, the g th group has $i \binom{i-1}{g-j-1} \binom{k-i}{j}$ terms having
 377 the form $(-1)^{g+1} \frac{1}{k-g+1} x_1^{k-j} x_k^j$. If $j \geq \frac{k}{2}$, from $k-j+1$ st
 378 to j th group, the g th group has $(k-i) \binom{k-i-1}{j-k+g-1} \binom{i}{k-j}$
 379 terms having the form $(-1)^{g+1} \frac{1}{k-g+1} x_1^{k-j} x_k^j$, from
 380 $j+1$ th to $j+i$ th group, $i+j < k$, the g th group
 381 has $i \binom{i-1}{g-j-1} \binom{k-i}{j} + (k-i) \binom{k-i-1}{j-k+g-1} \binom{i}{k-j}$ terms having
 382 the form $(-1)^{g+1} \frac{1}{k-g+1} x_1^{k-j} x_k^j$. The final k th group
 383 is the term $(-1)^{k-1} (k-1) x_1^i x_k^{k-i}$. So, if $i+j = k$,
 384 $j \geq \frac{k}{2}$, $i \leq \frac{k}{2}$, the summed coefficient of $x_1^i x_k^{k-i}$ is
 385 $(-1)^{k-1} (k-1) + \sum_{g=i+1}^{k-1} (-1)^{g+1} \frac{1}{k-g+1} (k-i) \binom{k-i-1}{g-i-1} +$
 386 $\sum_{g=k-i+1}^{k-1} (-1)^{g+1} \frac{1}{k-g+1} i \binom{i-1}{g-k+i-1} = (-1)^{k-1} (k-1) +$
 387 $(-1)^{k+1} + (k-i)(-1)^k + (-1)^k (i-1) =$
 388 $(-1)^{k+1}$. The summation identities are
 389 $\sum_{g=i+1}^{k-1} (-1)^{g+1} \frac{1}{k-g+1} (k-i) \binom{k-i-1}{g-i-1} =$
 390 $(k-i) \int_0^1 \sum_{g=i+1}^{k-1} (-1)^{g+1} \binom{k-i-1}{g-i-1} t^{k-g} dt =$
 391 $(k-i) \int_0^1 ((-1)^i (t-1)^{k-i-1} - (-1)^{k+1}) dt =$
 392 $(k-i) \left(\frac{(-1)^k}{i-k} + (-1)^k \right) = (-1)^{k+1} + (k-i)(-1)^k$
 393 and $\sum_{g=k-i+1}^{k-1} (-1)^{g+1} \frac{1}{k-g+1} i \binom{i-1}{g-k+i-1} =$
 394 $\int_0^1 \sum_{g=k-i+1}^{k-1} (-1)^{g+1} i \binom{i-1}{g-k+i-1} t^{k-g} dt =$
 395 $\int_0^1 (i(-1)^{k-i} (t-1)^{i-1} - i(-1)^{k+1}) dt = (-1)^k (i-1)$.
 396 If $j < \frac{k+1-i}{2}$, $i > k-1$, if $i = k$, $\psi_k = 0$, if $\frac{k+1-i}{2} \leq j \leq \frac{k-1}{2}$,
 397 $\frac{k+1}{2} \leq i \leq k-1$, the summed coefficient of $x_1^i x_k^{k-i}$ is
 398 $(-1)^{k-1} (k-1) + \sum_{g=k-i+1}^{k-1} (-1)^{g+1} \frac{1}{k-g+1} i \binom{i-1}{g-k+i-1} +$
 399 $\sum_{g=i+1}^{k-1} (-1)^{g+1} \frac{1}{k-g+1} (k-i) \binom{k-i-1}{g-i-1}$, the same as above. If
 400 $i+j < k$, since $\binom{i}{k-j} = 0$, the related terms can be ignored, so,
 401 using the binomial theorem and beta function, the summed co-
 402 efficient of $x_1^{k-j} x_k^j$ is $\sum_{g=j+1}^{i+j} (-1)^{g+1} \frac{1}{k-g+1} i \binom{i-1}{g-j-1} \binom{k-i}{j} =$
 403 $i \binom{k-i}{j} \int_0^1 \sum_{g=j+1}^{i+j} (-1)^{g+1} \binom{i-1}{g-j-1} t^{k-g} dt =$
 404 $\binom{k-i}{j} i \int_0^1 ((-1)^j t^{k-j-1} \left(\frac{t}{i-1} \right)^{1-i}) dt =$
 405 $\binom{k-i}{j} i \frac{(-1)^{j+i+1} \Gamma(i) \Gamma(k-j-i+1)}{\Gamma(k-j+1)} = \frac{(-1)^{j+i+1} i! (k-j-i)! (k-i)!}{(k-j)! j! (k-j-i)!} =$
 406 $(-1)^{j+i+1} \frac{i! (k-i)!}{k!} \frac{k!}{(k-j)! j!} = \binom{k}{i}^{-1} (-1)^{1+i} \binom{k}{j} (-1)^j$.
 407 The coefficient of $x_1^i x_k^{k-i}$ in $\binom{k}{i}^{-1} (-1)^{1+i} (x_1 - x_k)^k$
 408 is $\binom{k}{i}^{-1} (-1)^{1+i} \binom{k}{i} (-1)^{k-i} = (-1)^{k+1}$, same as the
 409 summed coefficient if $i+j = k$. If $i+j < k$,
 410 the coefficient of $x_1^{k-j} x_k^j$ is $\binom{k}{i}^{-1} (-1)^{1+i} \binom{k}{j} (-1)^j$,
 411 same as the corresponding summed coefficient. There-
 412 fore, $\psi_k(x_1 = x_1, \dots, x_i = x_1, x_{i+1} = x_k, \dots, x_k = x_k) =$
 413 $\binom{k}{i}^{-1} (-1)^{1+i} (x_1 - x_k)^k$, the maximum and minimum of ψ_k
 414 follow directly from the properties of the binomial coeffi-
 415 cient. \square

416 ξ_Δ is closely related to $f_\Xi(\Delta)$, which is the pairwise differ-
 417 ence distribution, since the probability density of ξ_Δ can be ex-
 418 pressed as $f_\Xi(\Delta|\Delta)$ and $\sum_{\bar{\Delta} = -(\frac{k}{3+(\frac{k-1}{2})})^{-1}(-\Delta)^k}^{\frac{1}{k}(-\Delta)^k} f_\Xi(\bar{\Delta}|\Delta) =$
 419 $f_\Xi(\Delta)$. Recall that $f_\Xi(\Delta)$ is monotonic increasing with a mode
 420 at the origin if the original distribution is unimodal. Thus, in
 421 general, ignoring the shape of ξ_Δ , Ξ_k is monotonic left and
 422 right around zero. In fact, the median of Ξ_k is also close to

423 zero, as it can be cast as a weighted mean of the medians
 424 of ξ_Δ . When Δ is small, all values of ξ_Δ are close to zero,
 425 resulting in the median of ξ_Δ being close to zero as well. When
 426 Δ is large, the median of ξ_Δ depends on its skewness, but the
 427 corresponding weight is much smaller, so even if ξ_Δ is highly
 428 skewed, the median of Ξ_k will only be slightly shifted from
 429 zero. Denote the median of Ξ_k as m_{Ξ_k} , for the five parametric
 430 distributions here, $|m_{\Xi_k}|$ s are all $\leq 0.1\sigma$ for Ξ_3 and Ξ_4 (SI
 431 Dataset S1). Assuming $m_{\Xi_k} = 0$, for the even ordinal central
 432 moment kernel distribution, the average probability density
 433 on the left side of zero is greater than that on the right side,
 434 since $\frac{1}{\binom{k}{2}^{-1}(Q(0)-Q(1))^k} > \frac{1}{\frac{1}{k}(Q(0)-Q(1))^k}$. This means that,
 435 on average, the inequality $f(Q(\epsilon)) \geq f(Q(1-\epsilon))$ holds. For
 436 the odd ordinal distribution, the discussion is harder since
 437 it is generally symmetric. Just consider Ξ_3 , let $x_1 = Q(p_i)$
 438 and $x_3 = Q(p_j)$, changing the value of x_2 from $Q(p_i)$ to
 439 $Q(p_j)$ will monotonically change the value of $\psi_3(x_1, x_2, x_3)$,
 440 since $\frac{\partial \psi_3(x_1, x_2, x_3)}{\partial x_2} = -\frac{x_1^2}{2} - x_1 x_2 + 2x_1 x_3 + x_2^2 - x_2 x_3 - \frac{x_3^2}{2}$,
 441 $-\frac{3}{4}(x_1 - x_3)^2 \leq \frac{\partial \psi_3(x_1, x_2, x_3)}{\partial x_2} \leq -\frac{1}{2}(x_1 - x_3)^2 \leq 0$. If the
 442 original distribution is right-skewed, ξ_Δ will be left-skewed,
 443 so, for Ξ_3 , the average probability density of the right side of
 444 zero will be greater than that of the left side, which means, on
 445 average, the inequality $f(Q(\epsilon)) \leq f(Q(1-\epsilon))$ holds (the same
 446 result can be inferred from the definition of central moments,
 447 the positive of odd order central moment is directly related
 448 to the left-skewness of the corresponding kernel distribution).
 449 In all, the monotonicity of the pairwise difference distribution
 450 guides the general shape of the k th central moment kernel dis-
 451 tribution, $k > 2$, forcing it to be unimodal-like with mode and
 452 median close to zero, then, the inequality $f(Q(\epsilon)) \leq f(Q(1-\epsilon))$
 453 or $f(Q(\epsilon)) \geq f(Q(1-\epsilon))$ holds in general. If a distribution is
 454 ordered and all of its central moment kernel distributions are
 455 also ordered, it is called completely ordered. Although strict
 456 complete orderliness is difficult to prove, even the inequality
 457 may be violated in a small range, as discussed in Subsection
 458 A, the mean-SWA $_{\epsilon}$ -median inequality remains valid, in most
 459 cases, for the central moment kernel distribution.

460 Another key property of the central moment kernel distri-
 461 bution, location invariant, is introduced in the next theorem.
 462 The proof is provided in the SI Text.

Theorem B.3. $\psi_k(x_1 = \lambda x_1 + \mu, \dots, x_k = \lambda x_k + \mu) =$
 463 $\lambda^k \psi_k(x_1, \dots, x_k)$. 464

Consider two continuous distributions belonging to the
 same location-scale family, their corresponding k th central
 moment kernel distributions only differ in scaling. So d is
 invariant, as shown in Subsection A. The recombined k th
 central moment, based on rm , is defined by,

$$rkm_{d,\epsilon,n} := (d+1) \text{SW}km_{\epsilon,n} - dmkm_{\epsilon,n},$$

where $\text{SW}km_{\epsilon,n}$ is using the binomial k th central moment
 ($Bkm_{\epsilon,n}$) here, $mkm_{\epsilon,n}$ is the median k th central moment.
 Since $\text{SW}km_{\epsilon,n}$ is an L -statistic, $rkm_{d,\epsilon,n}$ is an arithmetic
 I -statistic. Similarly, the quantile will not change after scaling.
 The quantile k th central moment is thus defined as

$$qkm_{d,\epsilon,n} := \hat{Q}_n \left(\left(p\text{SW}km - \frac{1}{2} \right) d + p\text{SW}km \right),$$

where $p\text{SW}km = \hat{F}_{\psi,n}(\text{SW}km_{\epsilon,n})$, $\hat{F}_{\psi,n}$ is the empirical cu-
 465 mulative distribution function of the corresponding central
 466 moment kernel distribution. $qkm_{d,\epsilon,n}$ is a quantile I -statistic. 467

Finally, for standardized moments, quantile skewness and quantile kurtosis are defined to be $qskew_{d,\epsilon,n} := \frac{qtm_{d,\epsilon,n}}{qsd_{d,\epsilon,n}^3}$ and $qkurt_{d,\epsilon,n} := \frac{qfm_{d,\epsilon,n}}{qsd_{d,\epsilon,n}^4}$. Quantile standard deviation ($qsd_{d,\epsilon,n}$), recombined standard deviation ($rsd_{d,\epsilon,n}$), quantile third central moment ($qtm_{d,\epsilon,n}$), quantile fourth central moment ($qfm_{d,\epsilon,n}$), recombined third central moment ($rtm_{d,\epsilon,n}$), recombined fourth central moment ($rfm_{d,\epsilon,n}$), recombined skewness ($rskew_{d,\epsilon,n}$), and recombined kurtosis ($rkurt_{d,\epsilon,n}$) are all defined similarly as above and not repeated here. The transformation to a location problem can also empower related statistical tests. From the better performance of the quantile mean in heavy-tailed distributions, quantile central moments are generally better than recombined central moments regarding asymptotic bias.

To avoid confusion, it should be noted that the robust location estimations of the kernel distributions discussed in this paper differ from the approach taken by Joly and Lugosi (2016) (40), which is computing the median of all U -statistics from different disjoint blocks based on the median of means technique, although asymptotically, as discussed in the previous article, it can be equivalent to the median U -statistic if the size of each block is equal to the degree of the kernel. Laforgue, Clemencon, and Bertail (2019) proposed the median of randomized U -statistics (40, 41), which is more sophisticated and closer to the median U -statistic if setting an additional constraint on the block size.

C. Congruent distribution. In the realm of nonparametric statistics, the precise values of robust estimators are of secondary importance. What is of primary importance is their relative differences or orders. Based on this principle, in the absence of contamination, as the parameters of the distribution vary, all reasonable nonparametric location estimates should asymptotically change in the same direction. Otherwise if the results based on trimmed mean are completely different from those based on the median, a contradiction arises. However, such contradictions are possible, for example, for the Weibull distribution, just consider the median and mean, $E[m] = \lambda \sqrt[3]{\ln(2)}$, $E[\mu] = \lambda \Gamma(1 + \frac{1}{\alpha})$, then, when $\alpha = 1$, $E[m] = \lambda \ln(2) \approx 0.693\lambda$, $E[\mu] = \lambda$, but when $\alpha = \frac{1}{2}$, $E[m] = \lambda \ln^2(2) \approx 0.480\lambda$, $E[\mu] = 2\lambda$, the mean increases, but the median decreases. To study the conditions that avoid such scenarios, let the quantile average function of a parametric distribution be denoted as $QA(\epsilon, \gamma, \alpha_1, \dots, \alpha_i, \dots, \alpha_k)$, where α_i represent the parameters of the distribution, then, a distribution is γ -congruent if and only if the sign of $\frac{\partial QA}{\partial \alpha_i}$ remains the same for all $0 \leq \epsilon \leq \frac{1}{1+\gamma}$. If this partial derivative is equal to zero or undefined, it can be considered both positive and negative, and thus does not impact the analysis. Asymptotically, any weighted average can be expressed as an integral of the quantile average function. Since the sign does not change after integration, the sign of $\frac{\partial QA}{\partial \alpha_i}$ remains the same for all $0 \leq \epsilon \leq \frac{1}{1+\gamma}$ implies that all γ -weighted averages change in the same direction as the parameters change, as long as they are not undefined. A distribution is completely γ -congruent if and only if it is γ -congruent and all its central moment kernel distributions are also γ -congruent. Setting $\gamma = 1$ constitutes the definitions of congruence and complete congruence. Chebyshev's inequality implies that, for any probability distribution with finite moments, even if some weighted averages change

in a direction different from that of the sample mean, the deviations are bounded. Additionally, distributions with infinite moments can be γ -congruent, since the definition is based on the quantile average, not the sample mean.

The following theorems show the conditions that a distribution is congruent or γ -congruent.

Theorem C.1. *If a distribution is γ -congruent, it is congruent.*

Proof. Any symmetric weighted average is also a weighted average. This concludes the proof. \square

Theorem C.2. *A symmetric distribution with a finite second moment is always congruent.*

Proof. For any symmetric distribution with a finite second moment, all symmetric quantile averages coincide. The conclusion follows immediately. \square

Theorem C.3. *A positive define location-scale distribution with a finite second moment is always γ -congruent.*

Proof. As shown in discussions in Subsection A, for a location-scale distribution, any weighted average can be expressed as $\lambda WA_0(\epsilon) + \mu$, where $WA_0(\epsilon)$ is an integral of $Q_0(p)$ according to the definition of the weighted average. Therefore, the derivatives with respect to the parameters λ or μ are always positive. By application of Theorem ??, the desired outcome is obtained. \square

Theorem C.4. *The second central moment kernel distribution derived from a continuous location-scale unimodal distribution with a finite second moment is always γ -congruent.*

Proof. Theorem B.3 shows that the corresponding central moment kernel distribution is also a location-scale family distribution. Theorem B.1 shows that it is positively defined. Implementing Theorem C.3 yields the desired result. \square

For the Pareto distribution, $\frac{\partial Q(p, \alpha)}{\partial \alpha} = \frac{x_m(1-p)^{-1/\alpha} \ln(1-p)}{\alpha^2}$. Since $\ln(1-p) < 0$ for all $0 < p < 1$, $(1-p)^{-1/\alpha} > 0$ for all $0 < p < 1$ and $\alpha > 0$, so $\frac{\partial Q(p, \alpha)}{\partial \alpha} < 0$, and therefore $\frac{\partial QA(\epsilon, \gamma, \alpha)}{\partial \alpha} < 0$, the Pareto distribution is γ -congruent. The derivative for the lognormal distribution is $\frac{\partial SQA(\epsilon, \sigma)}{\partial \sigma} = \frac{-\operatorname{erfc}^{-1}(2\epsilon)e^{\mu - \sqrt{2}\sigma \operatorname{erfc}^{-1}(2\epsilon)} - \operatorname{erfc}^{-1}(2-2\epsilon)e^{\mu - \sqrt{2}\sigma \operatorname{erfc}^{-1}(2-2\epsilon)}}{\sqrt{2}}$. Since the inverse complementary error function is positive when the input is smaller than 1, and negative when the input is larger than 1, $\operatorname{erfc}^{-1}(2\epsilon) = -\operatorname{erfc}^{-1}(2-2\epsilon)$, $e^{\mu - \sqrt{2}\sigma \operatorname{erfc}^{-1}(2-2\epsilon)} > e^{\mu - \sqrt{2}\sigma \operatorname{erfc}^{-1}(2\epsilon)}$, $\frac{\partial SQA(\epsilon, \sigma)}{\partial \sigma} > 0$, the lognormal distribution is congruent. Theorem C.2 implies that the generalized Gaussian distribution is congruent. For the Weibull distribution, when α changes from 1 to $\frac{1}{2}$, the average probability density on the left side of the median increases, since $\frac{\frac{1}{2}}{\lambda \ln(2)} < \frac{\frac{1}{2}}{\lambda \ln^2(2)}$, but the mean increases, indicating that the distribution is more heavy-tailed, the probability density of large values will also increase. The main reason for non-congruence of a right-skewed smooth partial bounded probability distribution lies in the simultaneous increase of probability densities on two opposite sides: one approaching the bound and the other approaching infinity. Note that the gamma distribution does not have this issue, it looks to be congruent.

Although some common parametric distributions are not congruent, Theorem C.3 establishes that γ -congruence always holds for a positive definite location-scale family distribution and thus for the second central moment kernel distribution generated from a continuous location-scale unimodal distribution as shown in Theorem C.4. Theorem B.2 demonstrates that all their central moment kernel distributions are unimodal-like with mode and median close to zero, as long as they are unimodal distributions. Assuming finite moments and constant $Q(0) - Q(1)$, increasing the mean of the kernel distribution will result in a more heavy-tailed distribution, i.e., the probability density of the values close to $\frac{1}{k}(-\Delta)^k$ will increase. While the total probability density on either side of zero will remain unchanged as the median is generally close to zero and much less impacted by increasing the mean, the probability density of the values close to zero will decrease. This transformation will increase nearly all symmetric weighted averages, in the general sense. Therefore, except for the median, which is assumed to be zero, nearly all symmetric weighted averages for all central moment kernel distributions derived from unimodal distributions should change in the same direction when the parameters change.

D. A two-parameter distribution as the consistent distribution.

Up to this point, consistent robust estimation has been limited to a parametric location-scale distribution. The location parameter is often omitted for simplicity. In 1894, Pearson (42) introduced a family of continuous probability distributions that are now often characterized by the square of the skewness and the kurtosis. A distribution specified by a shape parameter (denoted as α) and a scale parameter (denoted as λ) is often referred to as a two-parameter distribution. Weibull, gamma, Pareto, lognormal, and generalized Gaussian distributions are all two-parameter unimodal distributions. Since α and λ can be converted to skewness and kurtosis, a two-parametric distribution can also be fully specified by these standardized moments. Moreover, if α or skewness or kurtosis is a constant, the two-parameter distribution is reduced to a single-parameter distribution. The above discussion shows that, due to the invariant property, if a single-parameter distribution is chosen as the consistent distribution, the type of invariant moments and their related weighted moments are given, there should exist a unique k -tuple (d_{im}, \dots, d_{ikm}) calibrated by the distribution and the corresponding kernel distributions generated from this distribution. Since most common two-parameter distributions are always right skewed (if not, only the right skewed part is used, while the left skewed part is omitted), for a two-parameter distribution, let $D(|skewness|, kurtosis, k, etype, dtype, n) = d_{ikm}$ denote these relations, where the first input is the absolute value of the skewness, the second input is the kurtosis, the third is the order of the central moment (if $k = 1$, the mean), the fourth is the type of estimator, the fifth is the type of consistent distribution, and the sixth input is the sample size. For simplicity, the last three inputs will be omitted in the following discussion. Hold in awareness that specifying d values for a two-parameter distribution requires only skewness or kurtosis, so the other can also be omitted for simplicity.

For recombined moments, the object of using a two-parameter distribution as the consistent distribution is to find solutions for the system of equations

$$\begin{cases} rm(SWA, median, D(|rskew|, rkurt, 1)) = \mu \\ rvar(SWvar, mvar, D(|rskew|, rkurt, 2)) = \mu_2 \\ rtm(SWtm, mtm, D(|rskew|, rkurt, 3)) = \mu_3 \\ rfm(SWfm, mfm, D(|rskew|, rkurt, 4)) = \mu_4 \\ rskew = \frac{\mu_3}{\mu_2} \\ rkurt = \frac{\mu_4}{\mu_2^2} \end{cases}, \quad (640)$$

where μ_2 , μ_3 and μ_4 are the population second, third and fourth central moments. $|rskew|$ and $rkurt$ should be the invariant points of the functions

$$\varsigma(|rskew|) = \left| \frac{rtm(SWtm, mtm, D(|rskew|, 3))}{rvar(SWvar, mvar, D(|rskew|, 2))^{\frac{3}{2}}} \right| \quad \text{and} \quad (644)$$

$\varkappa(rkurt) = \frac{rfm(SWfm, mfm, D(rkurt, 4))}{rvar(SWvar, mvar, D(rkurt, 2))^2}$. Clearly, this is an overdetermined nonlinear system of equations, as the skewness and kurtosis are interrelated for a two-parameter distribution. Since an overdetermined system constructed with random coefficients is almost always inconsistent, it is natural to optimize them separately using the fixed-point iteration (see Algorithm 1, only $rkurt$ is provided, others are the same).

Algorithm 1 $rkurt$ for a two-parameter distribution

Input: D ; $SWvar$; $SWfm$; $mvar$; mfm ; $maxit$; δ

Output: $rkurt_{i-1}$

$i = 0$

2: $rkurt_i \leftarrow \varkappa(kurtosis_{max}) \triangleright$ Using the maximum kurtosis available in D as an initial guess.

repeat

4: $i = i + 1$

$rkurt_{i-1} \leftarrow rkurt_i$

6: $rkurt_i \leftarrow \varkappa(rkurt_{i-1})$

until $i > maxit$ or $|rkurt_i - rkurt_{i-1}| < \delta \quad \triangleright maxit$ is the maximum number of iterations, δ is a small positive number.

The following theorem shows the validity of Algorithm 1.

Theorem D.1. $|rskew|$ and $rkurt$, defined as the largest attracting fix points of the functions $\varsigma(|rskew|)$ and $\varkappa(rkurt)$, are consistent estimators of $\tilde{\mu}_3$ and $\tilde{\mu}_4$ for a righted skewed two-parameter distribution whose central moment kernel distributions are all congruent, as long as they are within the domain of D (finite), where $\tilde{\mu}_3$ and $\tilde{\mu}_4$ are the population skewness and kurtosis.

Proof. Without loss of generality, only $rkurt$ is considered here, while the logic for $|rskew|$ is the same. From the definition of D , $\frac{\varkappa(rkurt)}{rkurt} =$

$$\frac{\frac{\mu_{4,cali} - SWfm_{cali}}{SWfm_{cali} - mfm_{cali}} (SWfm - mfm) + SWfm}{\left(\frac{\mu_{2,cali} - SWvar_{cali}}{SWvar_{cali} - mvar_{cali}} (SWvar - mvar) + SWvar \right)^2}. \quad \text{Ac-} \quad (663)$$

cording to the property of invariance, assuming $\left(\frac{\mu_{2,cali} - SWvar_{cali}}{SWvar_{cali} - mvar_{cali}} (SWvar - mvar) + SWvar \right)^2 > 1$,

$$\text{then, } \frac{\varkappa(rkurt)}{rkurt} < \frac{\frac{\mu_{4,cali} - SWfm_{cali}}{SWfm_{cali} - mfm_{cali}} (SWfm - mfm) + SWfm}{rkurt} = \left(\frac{\frac{\mu_{4,cali} - SWfm_{cali}}{SWfm_{cali} - mfm_{cali}} (SWfm - mfm) + \frac{SWfm}{rkurt}}{rkurt} \right). \quad (667)$$

$$\lim_{rkurt \rightarrow \infty} \left(\frac{\frac{\mu_{4,cali} - SWfm_{cali}}{SWfm_{cali} - mfm_{cali}} (SWfm - mfm) + \frac{SWfm}{rkurt}}{rkurt} \right) \quad (668)$$

$$= \lim_{rkurt \rightarrow \infty} \left(\left(\frac{\mu_{4cali} - SWfm_{cali}}{rkurt} \right) \frac{SWfm - mfm}{SWfm_{cali} - mfm_{cali}} \right) = \lim_{rkurt \rightarrow \infty} \left(\left(\frac{(\mu_{4cali} - SWfm_{cali})\mu_{2cali}^2}{\mu_{4cali}} \right) \frac{SWfm - mfm}{SWfm_{cali} - mfm_{cali}} \right).$$

Since $SWfm_{cali}$ and mfm_{cali} are from the same kernel distribution as $\mu_{4cali} = rkurt\mu_{2cali}^2$, so an increase in μ_{4cali} will also result in an increase in $SWfm_{cali}$ and hence $SWfm_{cali} \gg SWfm$. Furthermore, Theorem B.2 and qualitative discussion in Subsection B shows that mfm_{cali} is close to zero, so, $\lim_{rkurt \rightarrow \infty} \left(\frac{SWfm - mfm}{SWfm_{cali} - mfm_{cali}} \right) < 1$. Also, according to the property of invariance, assuming $\mu_{2cali} < 1$ (the $\mu_{4cali} = rkurt\mu_{2cali}^2$ can be adjusted while $rkurt$ remains unchanged), then $\lim_{rkurt \rightarrow \infty} \left(\frac{(\mu_{4cali} - SWfm_{cali})\mu_{2cali}^2}{\mu_{4cali}} \right) < 1$.

Therefore, $\lim_{rkurt \rightarrow \infty} \frac{\kappa(rkurt)}{rkurt} < 1$. As a result, if there is at least one fix point, let the largest one be fix_{max} , then it is attracting since $|\frac{\partial(\kappa(rkurt))}{\partial(rkurt)}| < 1$ for all $rkurt \in [fix_{max}, kurtosis_{max}]$.

Asymptotically, consider any $SWfm_{cali} > SWfm$, assuming $\mu_{2cali} < 1$, then $(\mu_{4cali} - SWfm_{cali}) \frac{SWfm - mfm}{SWfm_{cali} - mfm_{cali}} + SWfm < \frac{\mu_{4cali}}{\mu_{2cali}^2} = rkurt$, $\frac{\kappa(rkurt)}{rkurt} < 1$, the same logic applies, a consistent estimator must be the last attracting fix point, fix_{max} is the consistent estimator. \square

As a result of Theorem D.1, assuming continuity and congruence of the central moment kernel distributions, Algorithm 1 converges surely provided that a fix point exists within the domain of D . At this stage, D can only be approximated through a Monte Carlo study. Continuity can be ensured by using linear interpolation. One common encountered problem is that the domain of D depends on both the consistent distribution and the Monte Carlo study, so the iteration may halt at the boundary if the fix point is not within the domain. However, by setting a proper maximum number of iterations, the algorithm can return the optimal boundary value. For quantile moments, the logic is similar, if the percentiles do not exceed the breakdown point. If so, consistent estimation is impossible and the algorithm will stop due to maximum number of iterations. The fix point iteration is, in principle, similar to the iterative reweighting in Huber M-estimator, but an advantage of this algorithm is that the optimization is only related to the function of d value and is independent of the sample size (except for the quantile moments, which require re-computation of the quantile function, but this operation has a time complexity of $O(1)$ for a sorted sample). Since $|rskew|$ can specify d_{rm} after optimization, this enables the robust estimations of all four moments to reach a near-consistent level for common unimodal distributions (Table ??, SI Dataset S1), just using the Weibull distribution as the consistent distribution.

E. Variance. As the fundamental theorem in statistics, the central limit theorem states that the standard deviation of the limiting form of the sampling distribution of the sample mean is $\frac{\sigma}{\sqrt{n}}$. The principle was later applied to the sampling distributions of robust location estimators (2, 36, 43–50) and it was found that the efficiencies of the robust location estimators can differ significantly from that of the arithmetic mean. Daniell (1920) stated (43) that comparing the efficiencies of various kinds of estimators is useless unless they all tend to coincide asymptotically. Bickel and Lehmann argued, also

in the landmark series (49, 50), that meaningful comparisons can be made by studying the standardized variance, asymptotic variances, and sharp lower bounds of these estimators. Here, the scaled standard error (SSE) is proposed to estimate the variances of all estimators, including recombined/quantile moments, on a scale similar to that of the sample mean.

Definition E.1 (Scaled standard error). Let $\mathcal{M}_{s_i s_j} \in \mathbb{R}^{i \times j}$ denote the sample-by-statistics matrix, i.e., the first column is the main statistics of interest, $\widehat{\theta}_m$, the second to the j th column are $j - 1$ statistics required to scale, $\widehat{\theta}_{r_1}, \widehat{\theta}_{r_2}, \dots, \widehat{\theta}_{r_{j-1}}$. Then, the scaling factor $\mathcal{S} = \left[1, \frac{\theta_{r_1}}{\theta_m}, \frac{\theta_{r_2}}{\theta_m}, \dots, \frac{\theta_{r_{j-1}}}{\theta_m} \right]^T$ is a $j \times 1$ matrix, which $\bar{\theta}$ is the mean of the column. The normalized matrix is $\mathcal{M}_{s_i s_j}^N = \mathcal{M}_{s_i s_j} \mathcal{S}$. The SSEs are the unbiased standard deviations of the corresponding columns.

Setting the bootstrap moments as the main statistics of interest, the SSEs of all robust estimators proposed here are often between those of the median moments and those of the unbiased sample moments (SI Dataset S1). This is because similar monotonic relations between robustness and variance are also very common, e.g., Bickel and Lehmann (50) proved that a lower bound for the efficiency of TM_e to sample mean is $(1 - 2\epsilon)^2$ and this monotonic bound is valid for any distribution. Lai, Robbins, and Yu (1983) proposed an estimator that adaptively chooses the mean or median in a symmetric distribution and showed that the result is typically as good as the better of the sample mean and median regarding variance (51). It can be interpreted as an attempt to use the variance version of the mean-SWA-median inequality. While they used bootstrap standard error as the criterion, another approach can be dated back to Laplace (1812) (52) is using a linear combination of median and mean and the weight is deduced to achieve minimum variance; examples for symmetric distributions see Samuel-Cahn (1994), Chan and He (1994), and Damilano and Puig (2004)'s papers (53–55).

The scaled standard error allows for direct comparison of variances for different location estimators in asymmetric distributions. In this study, twelve possible combinations were created using two invariant means and related symmetric weighted averages ($BM_{\frac{1}{8}}, SQM_{\frac{1}{8}}, BM_{\nu=2, \epsilon=\frac{1}{8}}, WM_{\frac{1}{8}}, BWM_{\frac{1}{8}}$, and $TM_{\frac{1}{8}}$ used here). Each combination has a SSE for a single-parameter distribution, which can be inferred through a Monte Carlo study. Then, the combination with the smallest SSE is chosen (if the percentiles of quantile moments exceed the breakdown point, this combination will be excluded). Theoretically, bootstrap is the optimal way to infer the variance-optimal choice without distributional assumptions, however, its computational cost is high. Similar to Subsection D, let $I(|skewness|, kurtosis, k, dtype, n) = ikm_{WA}$ denote these relations. Then since $\lim_{rkurt \rightarrow \infty} \frac{I(rkurt, 4)}{I(rkurt, 2)^2 rkurt} < 1$, the same fix point iteration algorithm can be used to choose the variance-optimum combination. The only difference is that unlike D , I is defined to be discontinuous but linear interpolation can also ensure continuity. Using this approach, the result is often very close to the optimum choice (SI Dataset S1).

Due to combinatorial explosion, the bootstrap (56), introduced by Efron in 1979, is indispensable for computing invariant moments in practice. In 1981, Bickel and Freedman (57) showed that the bootstrap is asymptotically valid to approximate the original distribution in a wide range of situations, including U -statistics. The limit laws of bootstrapped

784 trimmed U -statistics were proven by Helmers, Janssen, and
 785 Veraverbeke (1990) (58). In the previous article, the advan-
 786 tages of quasi-bootstrap were discussed (59–61). By using
 787 quasi-sampling, the impact of the number of repetitions of
 788 the bootstrap, or bootstrap size, on variance is negligible
 789 (SI Dataset S1). An estimator based on the quasi-bootstrap
 790 approach can be seen as a complex deterministic estimator
 791 that is not only computationally efficient but also statistical
 792 efficient. The only drawback of quasi-bootstrap compared
 793 to non-bootstrap is that a small bootstrap size can produce
 794 additional finite sample bias but this can be corrected by recal-
 795 ibrating the d values (SI Text). The default bootstrap size is
 796 set as 18 thousand here, as it balances computational cost and
 797 finite sample bias, except for the asymptotic value calculation.
 798 In general, the variances of invariant central moments are
 799 much smaller than those of corresponding unbiased sample
 800 central moments (deduced by Cramér (62)), except that of
 801 the corresponding second central moment (Table ??).

802 **Data Availability.** Data for Table ?? are given in SI Dataset S1.
