

# Near-consistent robust estimations of moments for unimodal distributions

**Descriptive statistics for parametric models currently heavily rely on the accuracy of distributional assumptions. Here, based on the invariant structures of unimodal distributions, a series of sophisticated yet efficient estimators, robust to both gross errors and departures from parametric assumptions, are proposed for estimating mean and central moments with insignificant asymptotic biases for common unimodal distributions. This article also illuminates the understanding of the common nature of probability distributions and the measures of them.**

The asymptotic inconsistencies between sample mean ( $\bar{x}$ ) and nonparametric robust location estimators in asymmetric distributions on the real line have been noticed for more than two centuries (1), yet remain unsolved. Strictly speaking, it is unsolvable as by trimming, some information about the original distribution is removed, making it impossible to estimate the values of the removed parts without distributional assumptions. Newcomb (1886, 1912) provided the first modern approach to robust parametric estimation by developing a class of estimators that gives "less weight to the more discordant observations" (2, 3). In 1964, Huber (4) used the minimax procedure to obtain M-estimator for the contaminated normal distribution, which has played a pre-eminent role in the later development of robust statistics. However, as previously demonstrated, under growing asymmetric departures from normality, the bias of the Huber M-estimator increases rapidly. This is a common issue in parameter estimations. For example, He and Fung (1999) constructed (5) a robust M-estimator for the two-parameter Weibull distribution, from which all moments can be calculated. Nonetheless, it is inadequate for the gamma, Perato, lognormal, and the generalized Gaussian distributions (SI Dataset S1). Another old and interesting approach is based on  $L$ -statistics, such as percentile estimators. Examples of percentile estimators for the Weibull distribution, the reader is referred to Menon (1963) (6), Dubey (1967) (7), Hassanein (1971) (8), Marks (2005) (9), and Boudt, Caliskan, and Croux (2011) (10)'s works. At the outset of the study of percentile estimators, it was known that they arithmetically utilizes the invariant structures of probability distributions (6, 11, 12). Maybe such estimators can be named as  $I$ -statistics. Formally, an estimator is classified as an  $I$ -statistic if it asymptotically satisfies  $I(LE_1, \dots, LE_l) = (\theta_1, \dots, \theta_q)$  for the distribution it is consistent, where LEs are calculated with the use of  $L$ -statistics,  $I$  is defined using arithmetic operations and constants, but it may also incorporate transcendental functions and quantile functions, and  $\theta$ s are the population parameters it estimates. A subclass of  $I$ -statistics, arithmetic  $I$ -statistics, is defined as LEs are  $L$ -statistics,  $I$  is solely defined using arithmetic operations and constants. Since some percentile estimators use the logarithmic function to transform all random variables

before computing the  $L$ -statistics, a percentile estimator might not always be an arithmetic  $I$ -statistic (7). In this article, two subclasses of  $I$ -statistics are introduced, arithmetic  $I$ -statistics and quantile  $I$ -statistics. Examples of quantile  $I$ -statistics will be discussed later. Based on  $L$ -statistics,  $I$ -statistics are naturally robust. Compared to probability density functions (pdfs) and cumulative distribution functions (cdfs), the quantile functions of many parametric distributions are more elegant. Since the expectation of a simple  $L$ -statistic can be expressed as an integral of the quantile function,  $I$ -statistics are often analytically obtainable. However, the performance of the aforementioned examples is often worse than that of the robust  $M$ -statistics when the distributional assumption is violated (SI Dataset S1). Even when distributions such as the Weibull and gamma belong to the same larger family, the generalized gamma distribution, a misassumption can still result in substantial biases for central moments, rendering the approach ill-suited.

In previous research on semiparametric robust mean estimation, median Hodges-Lehmann mean is still inconsistent for any skewed distribution, despite having much smaller asymptotic biases than other symmetric weighted  $L$ -statistics, which are either symmetric weighted averages or symmetric weighted H-L means. All robust location estimators commonly used are symmetric due to the universality of the symmetric distributions. An asymmetric weighted average is consistent for a semiparametric class of skewed distributions, but its lack of symmetry makes it suitable only for certain applications (13). Shifting from semiparametrics to parametrics, an ideal robust location estimator would have a non-sample-dependent breakdown point (defined in Subsection ??) and be consistent for any symmetric distribution and a skewed distribution with finite second moments. This is called an invariant mean. Based on the mean-symmetric weighted  $L$ -statistic-median inequality, the recombined mean is defined as

$$rm_{d,\epsilon,n,SWL} := \lim_{c \rightarrow \infty} \left( \frac{(SWL_{\epsilon,n} + c)^{d+1}}{(m_n + c)^d} - c \right),$$

## Significance Statement

Bias, variance, and contamination are the three main errors in statistics. Consistent robust estimation is unattainable without parametric assumptions. Here, invariant moments are proposed as a means of achieving near-consistent and robust estimations of moments, even in scenarios where moderate violations of distributional assumptions occur, while the variances are sometimes smaller than those of the sample moments.

where  $d$  is the key factor for bias correction,  $m_n$  is the sample median,  $\text{SWL}_{\epsilon,n}$  is  $\text{BM}_{\epsilon,n}$  in the first Subsection, but other symmetric weighted  $L$ -statistics can also be used in practice as long as the inequalities hold. The following theorem shows the significance of this arithmetic  $I$ -statistic.

**Theorem .1.** *If the second moments are finite,  $rm_{d \approx 0.163, \epsilon = \frac{1}{16}, \text{BM}}$  is a consistent mean estimator for the exponential and any symmetric distributions and the Pareto distribution with quantile function  $Q(p) = x_m(1-p)^{-\frac{1}{\alpha}}$ ,  $x_m > 0$ , when  $\alpha \rightarrow \infty$ .*

*Proof.* Finding  $d$  and  $\epsilon$  that make  $rm_{d,\epsilon}$  a consistent mean estimator is equivalent to finding the solution of  $E[rm_{d,\epsilon,n}] = E[X]$ . Rearranging the definition,  $rm_{d,\epsilon,\text{BM}} = \lim_{c \rightarrow \infty} \left( \frac{(\text{BM}_{\epsilon} + c)^{d+1}}{(m+c)^d} - c \right) = (d+1)\text{BM}_{\epsilon} - dm = \mu$ . So,  $d = \frac{\mu - \text{BM}_{\epsilon}}{\text{BM}_{\epsilon} - m}$ . The quantile function of the exponential distribution is  $Q(p) = \ln\left(\frac{1}{1-p}\right)\lambda$ .  $E[X] = \lambda$ .  $E[m_n] = Q\left(\frac{1}{2}\right) = \ln 2\lambda$ . For the exponential distribution,  $E\left[\text{BM}_{\frac{1}{16},n}\right] = \lambda \left(1 + \ln\left(\frac{16866160640 \sqrt[4]{\frac{5}{39}}}{1744156557 \cdot 11^{3/4}}\right)\right)$ , the detailed formula is given

in the SI Text. Obviously, the scale parameter  $\lambda$  can be canceled out,  $d = \frac{1 - \left(1 + \ln\left(\frac{16866160640 \sqrt[4]{\frac{5}{39}}}{1744156557 \cdot 11^{3/4}}\right)\right)}{\left(1 + \ln\left(\frac{16866160640 \sqrt[4]{\frac{5}{39}}}{1744156557 \cdot 11^{3/4}}\right)\right) - \ln 2} \approx 0.163$ . The

proof of the second assertion follows directly from the co-incidence property. For any symmetric distribution with a finite second moment,  $E[\text{BM}_{\epsilon,n}] = E[m_n] = E[X]$ . Then  $E[rm_{d,\epsilon,n,\text{BM}}] = \lim_{c \rightarrow \infty} \left( \frac{(E[X] + c)^{d+1}}{(E[X] + c)^d} - c \right) = E[X]$ . The proof for the Pareto distribution is more general. The mean of the Pareto distribution is given by  $\frac{\alpha x_m}{\alpha - 1}$ . The  $d$  value with two unknown percentiles  $p_1$  and  $p_2$  for the Pareto distribution

is  $d_{\text{Pareto}} = \frac{\frac{\alpha x_m}{\alpha - 1} - x_m(1-p_1)^{-\frac{1}{\alpha}}}{x_m(1-p_1)^{-\frac{1}{\alpha}} - x_m(1-p_2)^{-\frac{1}{\alpha}}}$ . Since any weighted  $L$ -statistic can be expressed as an integral of the quantile function as shown in Theorem A.1,  $\lim_{\alpha \rightarrow \infty} \frac{\frac{\alpha}{\alpha-1} - (1-p_1)^{-1/\alpha}}{(1-p_1)^{-1/\alpha} - (1-p_2)^{-1/\alpha}} = \frac{\ln(1-p_1) + 1}{\ln(1-p_1) - \ln(1-p_2)}$ , the  $d$  value for the Pareto distribution approaches that of the exponential distribution as  $\alpha \rightarrow \infty$ , regardless of the type of weighted  $L$ -statistic used. This completes the demonstration.  $\square$

Theorem .1 implies that for the Weibull, gamma, Pareto, lognormal and generalized Gaussian distribution,  $rm_{d \approx 0.163, \epsilon = \frac{1}{16}, \text{BM}}$  is consistent for at least one particular case. The biases of  $rm_{d \approx 0.163, \epsilon = \frac{1}{16}, \text{BM}}$  for distributions with skewness between those of the exponential and symmetric distributions are tiny (SI Dataset S1).  $rm_{d \approx 0.163, \epsilon = \frac{1}{16}, \text{BM}}$  exhibits excellent performance for all these common unimodal distributions (SI Dataset S1).

Besides introducing the concept of invariant mean, the purpose of this paper is to demonstrate that, in light of previous works, the estimation of central moments can be transformed into a location estimation problem by using  $U$ -statistics, the central moment kernel distributions possess desirable properties, and a series of sophisticated yet efficient robust estimators can be constructed whose biases are typically smaller than the variances (as seen in Table 1 for  $n = 4096$ ) for unimodal distributions.

## Background and Main Results

**A. Invariant mean.** It is well established that a theoretical model can be adjusted to fit the first two moments of the observed data. A continuous distribution belonging to a location-scale family takes the form  $F(x) = F_0\left(\frac{x-\mu}{\lambda}\right)$ , where  $F_0$  is a standard distribution without any shifts or scaling. Therefore,  $F(x) = Q^{-1}(x) \rightarrow x = Q(p) = \lambda Q_0(p) + \mu$ . Thus, any WA can be expressed as  $\lambda \text{WA}_0(\epsilon) + \mu$ , where  $\text{WA}_0(\epsilon)$  is an integral of  $Q_0(p)$  according to the definition of the weighted average. The following theorem shows that the Hodges-Lehmann distribution is always a location-scale distribution if the original distribution is a location-scale distribution with the same location and scale parameters. The proof is given in the SI Text.

**Theorem A.1.**  $hl_k(x_1 = \lambda x_1 + \mu, \dots, x_k = \lambda x_k + \mu) = \lambda hl_k(x_1, \dots, x_k) + \mu$ .

Let  $\text{WeHLM}_0(\epsilon)$  denote the expected value of weighted Hodges-Lehmann mean for the standard distribution, then for a location-scale family of distributions, it can also be expressed as  $\lambda \text{WeHLM}_0(\epsilon) + \mu$ . The simultaneous cancellation of  $\mu$  and  $\lambda$  in  $\frac{(\lambda \mu_0 + \mu) - (\lambda \text{SWL}_0(\epsilon) + \mu)}{(\lambda \text{SWL}_0(\epsilon) + \mu) - (\lambda m_0 + \mu)}$  assures that  $d$  is a constant. Consequently, the roles of  $\text{SWL}_{\epsilon}$  and median in  $rm_{d,\epsilon}$  can be replaced by any  $L$ -statistics, although only symmetric weighted  $L$ -statistics are considered in defining the invariant mean.

The performance in heavy-tailed distributions can be further improved by constructing the quantile mean as

$$qm_{d,\epsilon,n,\text{SWL}} := \hat{Q}_n \left( \left( \hat{F}_n(\text{SWL}_{\epsilon,n}) - \frac{1}{2} \right) d + \hat{F}_n(\text{SWL}_{\epsilon,n}) \right),$$

provided that  $\hat{F}_n(\text{SWL}_{\epsilon,n}) \geq \frac{1}{2}$ , where  $\hat{F}_n(x)$  is the empirical cumulative distribution function of the sample,  $\hat{Q}_n$  is the sample quantile function. The most popular method for computing the sample quantile function was proposed by Hyndman and Fan in 1996 (14). To minimize the finite sample bias, here,  $\hat{F}_n(x) := \frac{1}{n} \left( \frac{x - X_{sp}}{X_{sp+1} - X_{sp}} + sp \right)$ , where  $sp = \sum_{i=1}^n \mathbf{1}_{X_i \leq x}$ ,  $\mathbf{1}_A$  is the indicator of event  $A$ . The solution of  $\hat{F}_n(\text{SWL}_{\epsilon,n}) < \frac{1}{2}$  is reversing the percentile by  $1 - \hat{F}_n(\text{SWL}_{\epsilon,n})$ , the obtained percentile is also reversed. Without loss of generality, in the following discussion, only the case where  $\hat{F}_n(\text{SWL}_{\epsilon,n}) \geq \frac{1}{2}$  is considered. Moreover, in extreme righted skewed heavy-tailed distributions, the calculated percentile can exceed  $1 - \epsilon$ , the percentile will be modified to  $1 - \epsilon$  if this occurs. The quantile mean uses the location-scale invariant in a different way as shown in the following proof.

This table presents the use of the Weibull distribution as the consistent distribution plus optimization ( $ikm_v$  is invariant  $k$ th moment, variance-optimized) for five common unimodal distributions: Weibull, gamma, Pareto, lognormal and generalized Gaussian distributions. Robust location estimators highlighted in the previous article, unbiased sample moments and percentile estimator (PE) for the Weibull distribution (9) were used as comparisons. The Gaussian distribution was excluded for PE, since the logarithmic function does not produce results for negative inputs. The degree of the kernel of all weighted Hodges-Lehmann means is  $k = 4$ . The breakdown points of invariant moments are all  $\frac{1}{16}$  (not indicated). The table includes the average asymptotic bias (AAB, as  $n \rightarrow \infty$ ), root mean square error (RMSE, at  $n = 4096$ ), average bias (AB, at  $n = 4096$ ) and variance ( $SE \vee SSE$ , at  $n = 4096$ ) of these estimators, all reported in the units of the standard deviations of the distribution or corresponding kernel distributions. The notation  $bs$  indicates the quasi-bootstrap central moments. W means that the results were weighted by the number of Google Scholar search results on May 30, 2022 (including synonyms). The calibrations of  $d$  values and the computations of AAB, AB, and SSE were described in Subsection ??, ?? and SI Methods. Detailed results and related codes are available in SI Dataset S1 and [GitHub](#).
